

Modeling Current-Programmed Buck and Boost Regulators

R. D. MIDDLEBROOK, FELLOW, IEEE

Abstract—A general small-signal model for current-programmed switching power stages is used for design-oriented analysis of a 150-W buck regulator and of a 280-W boost regulator. The model, into which the current-programming minor feedback loop is absorbed, exposes the desired tendency towards “constant” output current. The regulator voltage loop remains the only explicit feedback loop, allowing the regulator closed-loop properties to be easily obtained from those of the open-loop current-programmed power stage. The design-oriented analytic results allow easy inference of the effects of element changes on the regulator performance functions. Results are obtained for the regulator line-to-output transfer function (audio susceptibility) and output impedance.

I. INTRODUCTION

CURRENT-PROGRAMMED switching power stages are becoming widely used in the power supply field because of several advantages they exhibit over conventional duty ratio programmed power stages [1], [2]. The design of switching regulators from the control loop aspect is now well understood: small-signal models for the power stage, and their use in design of the feedback loop, have gradually become familiar tools for design engineers over the last 15 years.

These well-known models and methods, however, are for duty ratio programmed power stages. Corresponding models for current-programmed power stages have appeared much more recently [3], [4] and have been the subject of some controversy [5], [6].

The purpose of this paper is to apply a particular small-signal model [6] of a current-programmed power stage to the analysis and design of a 150-W buck regulator and of a 280-W boost regulator. This is intended as an illustration of how the generalized model, established once and for all, can be applied not only to the analysis but also to the design of practical regulators.

Manuscript received May 4, 1988; revised August 9, 1988. This work was supported in part by GTE Communication Systems Corporation, Emerson Electric Company, IBM Tucson, and Motorola Government Electronics Division. This paper is a combination of two papers presented at the Power Electronics Show & Conference, October 1986, and the IEEE Applied Power Electronics Conference and Exposition, 1987.

The author is with the Department of Electrical Engineering, California Institute of Technology, Pasadena, CA 91125.
IEEE Log Number 8824136.

Although the loop gain is of central importance, a regulator is not specified directly by its loop gain, but by its performance functions such as output impedance and line-to-output transfer function (audiosusceptibility). Therefore, the objective of the analysis is to determine how the various component values affect these functions. Understanding of the physical significance of each analytic step is essential in choosing the numerous trade-offs that have to be made. This process and its objective, of course, are applicable to any design, and are central to the approach described as design-oriented analysis.

Most of the numbers in the example regulators are the same as those chosen by Schoneman and Mitchell [7]. This was done so that the performance functions determined here could be compared with those derived by Schoneman and Mitchell, who used an entirely different approach to the analysis. When all the numbers are the same, the performance functions obtained by the two approaches are, of course, also the same. In the examples discussed here, however, one parameter is chosen differently (the gain of the error amplifier) to illustrate its effect on the results.

The reasons leading to the choice of modeling approach are discussed in Section II and result in adoption of a canonical model that absorbs the current-programming minor feedback loop. In Section III, this y-parameter canonical model is modified and simplified to apply specifically to the buck power stage of the example regulator. From this model, the power-stage control-to-output and line-to-output transfer functions and output impedance are immediately written down.

In Section IV, the regulator voltage loop, which is now the only explicit feedback loop, is closed, and the loop gain T and feedback factor $1 + T$ are determined. The familiar properties of single-loop feedback systems are then employed to find the regulator closed-loop output impedance Z_{of} and line-to-output transfer function A_{rf} from their respective open-loop values. Also in Section IV, the results for the regulator closed-loop properties are evaluated.

In Sections V and VI, similar analyses and interpretations are conducted for the boost regulator example. Discussion of the results, of the effectiveness of the current-

programming function, and of the significance of the design-oriented analysis approach is presented in Section VII.

II. MODELING APPROACH

The circuit of the regulator with a current-programmed buck power stage is shown in Fig. 1, and that of the regulator with a current-programmed boost power stage is shown in Fig. 2. The numbers, supplied to the author by private communication, are those used in examples by Schoneman and Mitchell [7].

The power stages and the error amplifiers with gain controlled by local feedback are conventional. The reference voltage V_R is such that the steady-state duty ratio for each regulator is $D = 0.5$, which results in an output voltage $V = 15$ V from a line voltage $V_g = 30$ V for the buck and $V = 56$ V for $V_g = 28$ V for the boost. In the buck, a load resistance $R_L = 1.5 \Omega$ gives an output current of $I = 10$ A for an output power of 150 W, and for the boost $R_L = 11.2 \Omega$ gives $I = 5$ A for an output power of 280 W. The switching frequency is $f_s = \omega_s/2\pi = 25$ kHz, for a switching period $T_s = 1/f_s = 40 \mu\text{s}$.

Current-programming is implemented by R_s , which senses the switch current in the "on" condition. The resulting sensed voltage is multiplied by N , and a stabilizing ramp of peak value 2.0 V for the buck and 0.25 V for the boost is added before comparison with the control signal from the error amplifier. The operation of the current-programming feature and the purpose of the stabilizing ramp have been well documented [1], [6].

A. Choice of Feedback Loops

Current-programming establishes a local "minor" current feedback loop around the power stage, which is inside the "major" voltage feedback loop via the error amplifier. One may define and analyze any loops or combinations of loops one wishes, each of which has its own crossover frequency and phase margin [6]; the results for the regulator performance functions should of course be the same regardless of the loop definitions.

One choice is to consider the current and voltage loops to be in parallel around the power stage [4], [5]; this has the advantage that the familiar state-space averaged canonical model of the power stage under duty ratio programming [8] can be employed, but the disadvantage that the distinction between the current and voltage loops is lost. Since the two loops are employed for different purposes, loss of separation obscures the design criteria. Another choice is to consider the current loop separately, and to find a canonical model that represents overall transfer functions of the current-programmed power stage around which the regulator voltage loop is closed. This approach, recommended in [6], has the advantage that design and optimization of the voltage loop proceeds in the same way as for a duty ratio programmed power stage; there is

Fig. 1. Current-programmed buck regulator. Values of R_a and C_a are later chosen to be 270 k and 0.53 μF .

Fig. 2. Current-programmed boost regulator. Values of R_a and C_a are later chosen to be 72.2 k and 0.23 μF .

merely a different canonical model for the current-programmed power stage, whose contrasting properties are already explicitly exposed in the model, just as there is a different canonical model for the duty ratio programmed power stage in discontinuous conduction. Another advantage of this approach is that the analysis of the current loop is done once and for all and is represented by its canonical model; thereafter, design of any regulator requires consideration only of the voltage loop. This is the approach that will be adopted here.

The canonical small-signal model for current-programmed pulsewidth modulated (PWM) converters operated in the continuous conduction mode is shown in Fig. 3. This y-parameter model and a table of expressions for the element values for the buck, boost, and buck-boost converters, were presented in [6]. This becomes the starting point for the design-oriented analysis for the buck and boost regulators of Figs. 1 and 2.

Fig. 3. Generalized small-signal y parameter model for current-programmed power stage. Current-programming minor feedback loop around power stage is absorbed in, and therefore is implicit in, model. There are two inputs, small-signal control voltage \hat{v}_c and line voltage \hat{v}_g .

B. Current-Programmed Converter Canonical Model

For the buck converter the expressions for the six elements in the model of Fig. 3 are

$$\begin{aligned} y_{12} &= \frac{c_2 D}{R} \frac{1 + \frac{sD/c_2}{\omega_s/\pi}}{1 + \frac{s}{\omega_c}} & y_{21} &= -\frac{D(nD' - 1)}{KR} \frac{1}{1 + \frac{s}{\omega_c}} \\ y_{1c} &= \frac{D}{R_f} \frac{1 + \frac{sL}{R}}{1 + \frac{s}{\omega_c}} & y_{2c} &= -\frac{1}{R_f} \frac{1}{1 + \frac{s}{\omega_c}} \\ y_{11} &= \frac{c_1 D^2}{R} \frac{1 + \frac{s/c_1}{\omega_s/\pi}}{1 + \frac{s}{\omega_c}} & y_{22} &= \frac{nD' - D}{KR} \frac{1}{1 + \frac{s}{\omega_c}} \end{aligned} \quad (1)$$

where

$$c_1 \equiv 1 - \frac{nD' - 1}{K} \quad c_2 \equiv 1 - \frac{nD' - D}{K} \quad (2)$$

For the boost converter, the corresponding expressions are

$$\begin{aligned} y_{12} &= -\frac{nD'^2}{KR} \frac{1}{1 + \frac{s}{\omega_c}} & y_{21} &= -\frac{c_3}{D'R} \frac{1 + \frac{Ds/c_3}{\omega_s/\pi}}{1 + \frac{s}{\omega_c}} \\ y_{1c} &= \frac{1}{R_f} \frac{1}{1 + \frac{s}{\omega_c}} & y_{2c} &= -\frac{D'}{R_f} \frac{1 - \frac{sL}{D'^2 R}}{1 + \frac{s}{\omega_c}} \\ y_{11} &= \frac{nD' - D}{KR} \frac{1}{1 + \frac{s}{\omega_c}} & y_{22} &= \frac{1 + \frac{nD'^3}{K}}{R} \frac{1}{1 + \frac{s}{\omega_c}} \end{aligned} \quad (3)$$

where

$$c_3 \equiv 1 + \frac{D'^2(nD' - D)}{K} \quad (4)$$

The model of Fig. 3 and the above expressions represent the part of Fig. 1 or Fig. 2 designated the "power stage," that is, excluding the load resistance R_L and the load capacitance C and its associated esr. Also, the parasitic resistances within the power stage are neglected, which means that R_s is accounted for solely as a current sensing device, and its voltage drop in the power stage is ignored. The dc output voltage V in Fig. 1 or Fig. 2 is determined by two inputs, the line voltage V_g and the control voltage V_c . Similarly, in the small-signal model of Fig. 3, the small-signal output voltage \hat{v} is determined by the corresponding two small-signal inputs \hat{v}_g and \hat{v}_c .

There are several parameters in the expressions for the element values in addition to those that are explicit in Figs. 1 and 2. These are defined and evaluated below, along with a review of their significance in the operation of the current-programmed converter.

The current sensing function is represented by R_f , which is the ratio of the voltage presented to the comparator to the switch current (that is, the inductor current) that is being sensed. Because of the gain factor N , the effective value of R_f is $R_f = NR_s = 5 \times 0.02 = 0.10 \Omega$ for the buck converter of Fig. 1, and $R_f = 3.25 \times 0.025 = 0.0813 \Omega$ for the boost converter of Fig. 2.

The numerical parameter n relates the equivalent current slope M_c of the stabilizing ramp to the slope M_1 of the inductor current during the switch on-time:

$$n \equiv 1 + 2M_c/M_1 \quad (5)$$

Here, in the buck converter of Fig. 1, the ramp reaches a peak voltage V_p during a switching period T_s , so the equivalent current slope is $M_c = V_p/T_s R_f = 2.0/(40 \times 0.10) = 0.5 \text{ A}/\mu\text{s}$. The inductor current slope during the switch on-time, when the inductor is connected between line and output, is $M_1 = (V_g - V)/L = 15/40 = 0.375 \text{ A}/\mu\text{s}$. Hence $n = 1 + 2 \times 0.5/0.375 = 3.67$.

In the boost converter of Fig. 2, $M_c = V_p/T_s R_f = 0.25/(40 \times 0.0813) = 0.0769 \text{ A}/\mu\text{s}$. The inductor current slope during the switch on-time, when the inductor is connected across the line, is $M_1 = V_g/L = 28/195 = 0.144 \text{ A}/\mu\text{s}$. Hence $n = 1 + 2 \times 0.069/0.144 = 2.07$.

The purpose of the stabilizing ramp is to extend the range of stability of the current-programmed power stage beyond the value $D_{\max}/(1 - D_{\max}) = n$, so $D_{\max} = n/(1 + n)$. In the present buck converter case, $n = 3.67$ so $D_{\max} = 3.67/4.67 = 0.786$, which means that the minimum line voltage for which regulation of the output voltage $V = 15 \text{ V}$ can be maintained is $V/D_{\max} = 15/0.786 = 19.1 \text{ V}$. In the boost converter case, $n = 2.07$ so $D_{\max} = 2.07/3.07 = 0.674$, and the minimum line voltage for which regulation of the output voltage $V = 56 \text{ V}$ can be maintained is $(1 - D_{\max})V = V/(1 + n) = 56/3.07 = 18 \text{ V}$.

It is also shown in [6] that if the stabilizing ramp slope M_c equals the slope M_2 of the inductor current during the switch off-time, then any disturbance from the equilibrium duty ratio is eliminated in one switching period; the value $n = n_1$ corresponding to $M_c = M_2$ is $n_1 = (1 + D)/(1 - D) = 3$ for $D = 0.5$. In the present buck converter example, $n = 3.67$ so M_c exceeds M_2 , and in this sense the converter is "over-stabilized." However, in the boost converter $n = 2.07$ so M_c does not exceed M_2 , and the converter is "understabilized."

The frequency ω_c , which appears as a pole in all six y parameters, is given by

$$\omega_c = \frac{\omega_s}{\pi n D'} = \begin{cases} 2\pi \frac{25}{\pi \times 3.67 \times 0.5} = (2\pi)4.34 \text{ kHz} & \text{(buck)} \\ 2\pi \frac{25}{\pi \times 2.07 \times 0.5} = (2\pi)7.69 \text{ kHz} & \text{(boost).} \end{cases} \quad (6a) \quad (6b)$$

In [6], ω_c is identified as the crossover frequency of the loop gain of the minor current loop. This parameter represents the only visible evidence of the current feedback loop after the feedback effects have been absorbed into the y-parameter model of Fig. 3.

The resistance R is an "operating point parameter" defined as

$$R = \frac{\text{dc output voltage}}{\text{dc output current}} = \frac{V}{I} = \begin{cases} \frac{15}{10} = 1.5 \Omega & \text{(buck)} \\ \frac{56}{5} = 11.2 \Omega & \text{(boost).} \end{cases} \quad (7a) \quad (7b)$$

The operating point parameter affects the values of some of the elements in the model, as in any small-signal linearized model of a nonlinear system. For example, the emitter resistance in the Tee-model of a bipolar transistor is a function of the dc emitter current. In the present example, if the load on the regulator is a pure resistance R_L , then $R = R_L$ numerically. However, the distinction in symbols will be retained as a reminder that R and R_L are conceptually different; R is a parameter contained in the model of the power stage, whereas R_L is an external element. The distinction is important when the load contains a constant current component and/or becomes complex.

Finally, K is a "conduction parameter" defined as

$$K \equiv \frac{2L}{RT_s} = \begin{cases} \frac{2 \times 40}{1.5 \times 40} = 1.33 & \text{(buck)} \\ \frac{2 \times 195}{11.2 \times 40} = 0.871 & \text{(boost).} \end{cases} \quad (8a) \quad (8b)$$

As discussed in [6], the low-frequency loop gain of the current-programmed minor feedback loop is proportional

to K , and K is the same conduction parameter that appears in the canonical model for a duty ratio programmed power stage in discontinuous conduction mode. Here, it appears in the model for a current-programmed power stage in continuous conduction mode and must exceed a certain critical value K_{crit} if the discontinuous conduction mode is to be avoided.

It is shown in [9] that, for a buck converter $K_{\text{crit}} = D'$, and for a boost converter $K_{\text{crit}} = DD'^2$. In the present examples $D = 0.5$, so $K_{\text{crit}} = 0.5$ for the buck and $K_{\text{crit}} = 0.125$ for the boost. From (5) and (6), there is a corresponding minimum value I_{min} of dc load current:

$$I_{\text{min}} = \frac{VT_s}{2L} K_{\text{crit}} = \begin{cases} \frac{15 \times 40}{2 \times 40} 0.5 = 3.75 \text{ A} & \text{(buck)} \\ \frac{56 \times 40}{2 \times 195} 0.125 = 0.718 \text{ A} & \text{(boost).} \end{cases} \quad (9a) \quad (9b)$$

The corresponding maximum load resistance (again, for a pure resistance load) is

$$R_{L\text{max}} = R_{\text{max}} = \frac{V}{I_{\text{min}}} = \begin{cases} \frac{15}{3.75} = 4 \Omega & \text{(buck)} \\ \frac{56}{0.718} = 78 \Omega & \text{(boost).} \end{cases} \quad (10a) \quad (10b)$$

If the operating conditions of the buck converter in Fig. 1 represent full load power of 150 W at $I = 10$ A, the minimum load power to avoid discontinuous conduction is $3.75 \text{ A} \times 15 \text{ V} = 56 \text{ W}$, or about 38 percent of full load power. For the boost converter of Fig. 2, the minimum load power is $0.718 \text{ A} \times 56 \text{ V} = 40 \text{ W}$, or about 14 percent of full load power.

Analysis of the buck and boost regulators of Figs. 1 and 2 will now be discussed separately, in Sections III, IV, and V, VI respectively.

III. CURRENT-PROGRAMMED BUCK REGULATOR OPEN-LOOP PROPERTIES

A. Modified y-Parameter Model

The y-parameter expressions of (1) can be put into a somewhat more convenient form by elimination of the parameter K in favor of the power stage inductance L , by (6) and (8):

$$\frac{KR}{nD'} = \omega_c L. \quad (11)$$

For example, y_{22} can be written

$$1/y_{22} = \frac{\omega_c L}{1 - D/nD'} \left(1 + \frac{s}{\omega_c} \right). \quad (12)$$

The physical interpretation of $\omega_c L = 2\pi \times 4.34 \times 0.04 = 1.09 \Omega$ is that it is the reactance of the power stage inductance at the current loop gain crossover frequency.

It follows from (12) that $1/y_{22}$ consists of a resistance in series with an inductance. However, in the regulator circuit of Fig. 1, $1/y_{22}$, which is the output impedance of the power stage, is paralleled by C and R_L . As a consequence the inductive component y_{22} can be neglected because at frequencies where it becomes significant in y_{22} , the total parallel impedance is dominated by C . Hence (because of the way the power stage is loaded), $1/y_{22} \approx \omega_c L / (1 - D/nD') = 1.09/0.727 = 1.50 \Omega$.

Replacement of factors in K by $\omega_c L$, according to (11), in the other y parameters allows (1) to be rewritten in the following forms:

$$y_{12} = \frac{c_2 D}{R} \frac{1 + \frac{sD/c_2}{\omega_s/\pi}}{1 + \frac{s}{\omega_c}} \quad y_{21} = -\frac{D(1 - 1/nD')}{\omega_c L} \cdot \frac{1}{1 + \frac{s}{\omega_c}}$$

$$y_{1c} = \frac{D}{R_f} \frac{1 + \frac{sL}{R}}{1 + \frac{s}{\omega_c}} \quad y_{2c} = -\frac{1}{R_f} \frac{1}{1 + \frac{s}{\omega_c}}$$

$$y_{11} = -\frac{c_1 D^2}{R} \frac{1 + \frac{s/c_1}{\omega_s/\pi}}{1 + \frac{s}{\omega_c}} \quad y_{22} = \frac{1 - D/nD'}{\omega_c L} \quad (13)$$

where

$$c_1 = 1 - \frac{(1 - 1/nD')R}{\omega_c L} \quad c_2 = 1 - \frac{(1 - D/nD')R}{\omega_c L} \quad (14)$$

Fig. 4 shows the small-signal model of the current-programmed buck regulator of Fig. 1, incorporating the modifications already discussed. Since the regulator input properties seen by the line are not discussed in this paper, the input half of the y -parameter model is omitted; only the output half is needed to derive the loop gain, output impedance, and line-to-output transfer function. For convenience in application of this model, the numerical values already obtained are summarized below:

$$\begin{aligned} D &= 0.5 & R_f &= 0.10 \Omega \\ C &= 2700 \mu\text{F} & R &= R_L = 1.5 \Omega \\ f_c &= 4.34 \text{ kHz} & \omega_c L &= 1.09 \Omega. \end{aligned} \quad (15)$$

Fig. 4. Small-signal model of circuit of Fig. 1. y -parameter model of Fig. 2 is modified and simplified for buck converter, and input half is omitted. Voltage minor feedback loop around error amplifier is absorbed in, and therefore is implicit in, model represented by gain block A_1 . Only voltage major feedback loop remains explicit.

B. Open-Loop Transfer Functions A_c , A_g , and Z_o

The switch shown in Fig. 4 is introduced merely to permit separation between the open-loop and closed-loop properties. Three small-signal functions of the open-loop loaded power stage are of interest: the control-to-output transfer function $A_c \equiv \hat{v}/\hat{v}_c$, the line-to-output transfer function (audio susceptibility) $A_g \equiv \hat{v}/\hat{v}_g$, and the output impedance (including the load) Z_o . These functions are easily written down directly from the model of Fig. 3, and evaluated with use of (13)–(15):

$$A_c = A_{cm} \frac{1}{(1 + s/\omega_p)(1 + s/\omega_c)} \quad (16)$$

where

$$A_{cm} \equiv \frac{\frac{\omega_c L}{1 - D/nD'} \parallel R_L}{R_f} = \frac{1.51 \parallel 1.5}{0.10} = 7.5 \rightarrow 17.5 \text{ dB} \quad (17)$$

$$\omega_p \equiv \frac{1}{\left(\frac{\omega_c L}{1 - D/nD'} \parallel R_L \right) C} = \frac{10^3}{0.75 \times 2.7} = (2\pi) 79 \text{ Hz} \quad (18)$$

$$A_g = A_{gm} \frac{1}{(1 + s/\omega_p)(1 + s/\omega_c)} \quad (19)$$

where

$$A_{gm} = \frac{D(1 - 1/nD')}{\omega_c L} \left(\frac{\omega_c L}{1 - D/nD'} \parallel R_L \right) = 0.21 \times 0.75 = 0.16 \rightarrow -16 \text{ dB} \quad (20)$$

Fig. 5. Magnitude versus frequency asymptotes of open-loop loaded power stage transfer functions control-to-output $A_c \equiv \hat{v}/\hat{v}_c$, line-to-output $A_g \equiv \hat{v}/\hat{v}_g$, and output impedance Z_o , from model of Fig. 3.

$$Z_o \equiv R_{om} \frac{1}{1 + \frac{s}{\omega_p}} \quad (21)$$

where

$$R_{om} = \frac{\omega_c L}{1 - D/nD'} \parallel R_L = 0.75 \Omega \rightarrow -2.5 \text{ dB ref. } 1 \Omega. \quad (22)$$

These three functions are sketched in magnitude-asymptote form in Fig. 5.

IV. CURRENT-PROGRAMMED BUCK REGULATOR CLOSED-LOOP PROPERTIES

The model of Fig. 4 contains all the information necessary for the establishment of the major voltage loop gain and the regulator closed-loop output impedance Z_{of} and line-to-output transfer function A_{gf} .

A. Loop Gain T , Phase Margin ϕ_M , and Feedback Factor $1 + T$

The voltage loop gain T is simply the product of the error amplifier gain A_1 and the control-to-output transfer function A_c of the loaded power stage:

$$T = A_1 A_c. \quad (23)$$

If A_1 is a constant A_{1m} , the loop gain is merely a vertical scaling of the function A_c with its various corner frequencies. This is the same as saying that the value of A_{1m} determines not only the midband loop gain T_m as

$$T_m = A_{1m} A_{cm} \quad (24)$$

but also the loop gain crossover frequency $f_{vc} = v_{vc}/2\pi$,

the frequency where the magnitude of T crosses the 0-dB axis, as shown in Fig. 6. By the geometry of the graph,

$$\omega_{vc} = T_m \omega_p. \quad (25)$$

The value of A_{1m} must be chosen so that crossover occurs below the pole ω_c , because otherwise the phase margin would be too small. Obviously, one wishes to place the crossover frequency as high as possible to get the widest bandwidth over which the benefits of feedback are realized.

Where shall the loop gain crossover frequency f_{vc} be placed? Let us try putting f_{vc} at about one-third of the pole frequency $f_c = 3.34$ kHz, say $f_{vc} = 1.67$ kHz.

The resulting phase margin ϕ_M of the voltage loop gain is 180° minus the sum of the lag contributions from the poles at f_p and f_c :

$$\begin{aligned} \phi &= 180^\circ - \left(\tan^{-1} \frac{1670}{79} + \tan^{-1} \frac{1.67}{4.34} \right) \\ &= 180^\circ - (87^\circ + 21^\circ) = 72^\circ. \end{aligned} \quad (26)$$

This is an acceptable phase margin, so we can adopt the crossover frequency $f_{vc} = 1.67$ kHz and use (25) to find the corresponding midband loop gain as $T_m = f_{vc}/f_p = 1670/79 = 21.3 \rightarrow 26.5$ dB. From (24), the required value of the error amplifier gain is $A_{1m} = T_m/A_{cm} = 21.3/7.5 = 2.84 \rightarrow 9.1$ dB.

The error amplifier is actually an opamp with local feedback to set its overall gain A_1 and hence the crossover frequency of the regulator major voltage loop. Since only 9.1 dB of gain is required, most of the available opamp gain is wasted. However, the lost gain can be recovered, for frequencies sufficiently far below the regulator loop crossover frequency, by placing an "inverted zero" ω_1 in the error amplifier gain function:

$$A_1 = A_{1m} \left(1 + \frac{\omega_1}{s} \right). \quad (27)$$

From the circuit in Fig. 1,

$$A_{1m} = R_a/R_b \quad (28)$$

$$\omega_1 \equiv \frac{1}{C_a R_a}. \quad (29)$$

The zero ω_1 is open to choice; let us make $\omega_1/2\pi = f_1 = 11$ Hz. Since A_{1m} is already set at 2.84 and $R_b = 95.3$ K is specified, the required values of R_a and C_a are

$$R_a = A_{1m} R_b = 2.84 \times 95.3 = 270 \text{ k} \quad (30)$$

$$C_a = \frac{1}{\omega_1 R_a} = \frac{10^{-3}}{2\pi \times 11 \times 270} = 0.053 \mu\text{F}. \quad (31)$$

The final designed loop gain T is shown in Fig. 7. The inverted zero at $f_1 = 11$ Hz contributes a small additional phase lag $\tan^{-1}(11/1670) = 0.4^\circ$ at the crossover frequency $f_{vc} = 1.67$ kHz, resulting in a negligible reduction in the original phase margin $\phi_M = 72^\circ$.

The expression for the final regulator voltage loop gain,

Fig. 6. Placement of loop gain crossover frequency f_{vc} at 4.34 kHz, by appropriate choice of midband loop gain T_m and hence of error amplifier gain A_{1m} .

by incorporation of (16) and (27) into (23), is

$$T = T_m \frac{\left(1 + \frac{\omega_1}{s}\right)}{\left(1 + \frac{s}{\omega_p}\right)\left(1 + \frac{s}{\omega_c}\right)} \quad (32)$$

where

$$T_m \equiv A_{1m}A_{cm} = A_{1m} \frac{\frac{\omega_c L}{1 - D/nD'} \parallel R_L}{R_f} \quad (33)$$

$$= 21.3 \rightarrow 26.5 \text{ dB}. \quad (34)$$

Also, the regulator voltage loop crossover frequency is, from (18) and (25),

$$\omega_{vc} = T_m \omega_p = \frac{A_{1m}}{R_f C} \quad (35)$$

$$= \frac{2.84 \times 10^6}{0.10 \times 2700} = (2\pi) 1.67 \text{ kHz}. \quad (36)$$

The above numerical results for T_m and ω_{vc} of course confirm the values that led to the choice of A_{1m} in the first place. To complete the summary of analytical and numerical results, the expressions and numbers for the corner frequencies are repeated below:

$$\omega_p = \frac{1}{\left(\frac{\omega_c L}{1 - D/nD'} \parallel R_L\right) C} = (2\pi) 79 \text{ Hz} \quad (37)$$

$$\omega_c = \frac{\omega_s}{\pi n D'} = (2\pi) 4.34 \text{ kHz}. \quad (38)$$

One of the most important advantages of the adopted modeling approach is that the properties of the current-programmed power stage are already explicit before the

regulator major voltage loop is considered. The direct result of this approach is that the regulator closed-loop properties can be found from the open-loop properties by the familiar formulas for single-loop systems.

In particular, the regulator closed-loop output impedance Z_{of} and line-to-output transfer functions A_{gf} are given in terms of their respective open-loop values Z_o and A_g by

$$Z_{of} = \frac{Z_o}{1 + T} \quad (39)$$

$$A_{gf} = \frac{A_g}{1 + T} \quad (40)$$

where T is the regulator major voltage loop gain given by (32)–(38).

Only one additional calculation is required, which is to find the feedback factor $1 + T$ from the known T . This can be done very easily, to a sufficient degree of accuracy, by a semigraphical technique.

As shown in Fig. 7, $1 + T$ can be constructed by drawing the asymptotes for $1 + T$ just above those of T for frequencies below the crossover f_{vc} . However, beyond crossover, T is much less than unity, so $1 + T \approx 1$ or 0 dB. All that remains is to identify the corner frequencies of $1 + T$. The inverted zero f_1 and the lowest pole f_p are the same as those in T ; the new zero, by the geometry of the asymptotes, is $(1 + T_m)f_p$ or $(1 + T_m)f_{vc}/T_m$. Hence the factored pole-zero expression for $1 + T$ can be written by inspection of the asymptotes as

$$1 + T = (1 + T_m) \frac{\left(1 + \frac{\omega_1}{s}\right)\left(1 + \frac{T_m s}{(1 + T_m)\omega_{vc}}\right)}{\left(1 + \frac{s}{\omega_p}\right)} \quad (41)$$

Note that if (32) for T were substituted into $1 + T$ and the pole-zero factors found algebraically, a cubic equation would have to be solved. With appropriate approximation, the result of (41) would be obtained.

B. Closed-Loop Transfer Functions Z_{of} and A_{gf} for Maximum Load

The regulator closed-loop output impedance Z_{of} can now be found from substitution of (21) and (41) into (39):

$$Z_{of} = R_{ofm} \frac{1}{\left(1 + \frac{\omega_1}{s}\right)\left(1 + \frac{T_m s}{(1 + T_m)\omega_{vc}}\right)} \quad (42)$$

where

$$\begin{aligned} R_{ofm} &\equiv \frac{R_{om}}{1 + T_m} = \frac{T_m}{1 + T_m} \frac{R_{om}}{T_m} \\ &= \frac{T_m}{1 + T_m} \frac{R_f}{A_{1m}} = \frac{T_m}{1 + T_m} \frac{1}{\omega_{vc} C} \\ &= \frac{21.3}{22.3} \frac{0.10}{2.84} = 0.034 \Omega. \end{aligned} \quad (43)$$

Fig. 7. Construction of feedback factor $1 + T$ from loop gain T , after inverted zero chosen to be at $f_i = 11$ Hz has been introduced into T , for minimum load resistance $R_L = R = 1.5 \Omega$.

Fig. 8. Construction of closed-loop output impedance Z_{of} from its open-loop value Z_o and feedback factor $1 + T$, according to $Z_{of} = Z_o / (1 + T)$, for $R_L = R = 1.5 \Omega$.

Although the algebra is simple, more insight is gained into the above result if the process is conducted graphically. In Fig. 8, the magnitude asymptotes for Z_o and $1 + T$ are shown; their difference gives $Z_o / (1 + T) = Z_{of}$.

The same graphical process can be used to find the regulator closed-loop line-to-output transfer function. Fig. 9 shows the magnitude asymptotes of A_g and $1 + T$ from (19) and (41); their difference gives $A_g / (1 + T) = A_{gf}$. Analytically, the result is

$$A_{gf} = A_{gm} \frac{1}{\left(1 + \frac{\omega_l}{s}\right) \left(1 + \frac{T_m s}{(1 + T_m) \omega_{vm}}\right)} \quad (44)$$

Fig. 9. Construction of closed-loop line-to-output transfer function A_{gf} from its open-loop value A_g and feedback factor $1 + T$, according to $A_{gf} = A_g / (1 + T)$ for $R_L = R = 1.5 \Omega$.

where

$$\begin{aligned} A_{gf} &\equiv \frac{A_{gm}}{1 + T_m} = \frac{T_m}{1 + T_m} \frac{A_{gm}}{T_m} \\ &= \frac{T_m}{1 + T_m} \frac{D(1 - 1/nD')R}{A_{lm}\omega_c L} \\ &= \frac{T_m}{1 + T_m} \frac{D(1 - 1/nD')}{\omega_c L} \frac{1}{\omega_{vc} C} \\ &= \frac{21.3 \cdot 0.5 \times 0.455 \times 0.10}{22.3 \cdot 2.84 \times 1.09} \\ &= 0.0070 \rightarrow -43 \text{ dB}. \end{aligned} \quad (45)$$

V. CURRENT-PROGRAMMED BOOST REGULATOR OPEN-LOOP PROPERTIES

A. Modified y-Parameter Model

The y-parameter expressions of (3) can be put into a somewhat more convenient form. For example, y_{22} can be written

$$y_{22} = \left(\frac{1}{R} + \frac{nD'^3}{KR}\right) \left(1 + \frac{s}{\omega_c}\right). \quad (46)$$

From the definitions of ω_c and K , (6) and (8),

$$\frac{KR}{nD'^3} = \omega_c L_e \quad (47)$$

where

$$L_e = L/D'^2 = 195/0.5^2 = 780 \mu\text{H} \quad (48)$$

is the same "effective inductance" value that appears in the canonical model for the boost converter under duty

ratio programmed continuous conduction mode [8]. The physical interpretation of $\omega_c L_e = 2\pi \times 7.7 \times 0.780 = 37.7 \Omega$ is that it is the reactance of the effective inductance at the current loop gain crossover frequency.

It follows from (46) that $1/y_{22}$ consists of two resistances in parallel, $\omega_c L_e \parallel R$, in series with an inductance. However, in the regulator circuit of Fig. 1, $1/y_{22}$, which is the output impedance of the power stage, is paralleled by C and R_L . As a consequence, the inductive component of y_{22} can be neglected because at frequencies where it becomes significant in y_{22} , the total parallel impedance is dominated by C . Hence (because of the way the power stage is loaded), $1/y_{22} = \omega_c L_e \parallel R = 37.7/11.2 = 8.63 \Omega$.

Replacement of factors in K by $\omega_c L_e$, according to (47), in the other y parameters allows (3) to be rewritten in the following forms:

$$\begin{aligned} y_{12} &= -\frac{1}{D'\omega_c L_e} \frac{1}{1 + \frac{s}{\omega_c}} & y_{21} &= -\frac{c_3}{D'R} \frac{1 + \frac{s}{\omega_{zg}}}{1 + \frac{s}{\omega_c}} \\ y_{1c} &= \frac{1}{R_f} \frac{1}{1 + \frac{s}{\omega_c}} & y_{2c} &= -\frac{D'}{R_f} \frac{1 - \frac{s}{\omega_z}}{1 + \frac{s}{\omega_c}} \\ y_{11} &= \frac{1 - D/nD'}{D'^2 \omega_c L_e} \frac{1}{1 + \frac{s}{\omega_c}} & y_{22} &\approx \frac{1}{\omega_c L_e \parallel R} \end{aligned} \quad (49)$$

where

$$\begin{aligned} c_3 &= 1 + \frac{R(1 - D/nD')}{\omega_c L_e} \\ &= 1 + \frac{11.2(1 - 0.5/2.07 \times 0.5)}{37.7} = 1.15. \end{aligned} \quad (50)$$

There are two zeros in the expressions for the y parameters. That in y_{2c} is the same right half-plane (RHP) zero that occurs in the canonical model for the boost converter under duty ratio programming in continuous conduction mode [8], defined as

$$\omega_z = R/L_e = 11.2 \times 103/0.78 = (2\pi)2.29 \text{ kHz}. \quad (51)$$

The other zero is related to the switching frequency ω_s and is defined as

$$\omega_{zg} = \frac{c_3 \omega_s}{\pi D} = 2\pi \frac{1.15 \times 25}{\pi \times 0.5} = (2\pi)18.3 \text{ kHz}. \quad (52)$$

Fig. 10 shows the small-signal model of the current-programmed boost regulator of Fig. 2 incorporating the modifications already discussed. The input half of the y -parameter model is again omitted. The numerical values

Fig. 10. Small-signal model of circuit of Fig. 2. y -parameter model of Fig. 3 is modified and simplified for boost converter, and input half is omitted. Voltage minor feedback loop around error amplifier is absorbed in, and therefore is implicit in, model represented by gain block A_1 . Only voltage major feedback loop remains explicit.

already obtained are summarized as

$$\begin{aligned} c_3 &= 1.15 & f_c &= 7.19 \text{ kHz} & D &= 0.5 \\ R_f &= 0.0813 \Omega & f_z &= 2.23 \text{ kHz} & C &= 2000 \mu\text{F} \\ \omega_c L_e &= 37.7 \Omega & f_{zg} &= 18.3 \text{ kHz} & R &= R_L = 11.2 \Omega. \end{aligned} \quad (53)$$

B. Open-Loop Transfer Functions A_c , A_g , and Z_o

The three small-signal functions of the open-loop loaded power stage of interest are the control-to-output transfer function $A_c \equiv \hat{v}/\hat{v}_c$, the line-to-output transfer function (audiosusceptibility) $A_g \equiv \hat{v}/\hat{v}_g$, and the output impedance (including the load) Z_o . These functions are easily written down directly from the model of Fig. 10 and evaluated with the use of (53):

$$A_c = A_{cm} \frac{1 - s/\omega_z}{(1 + s/\omega_p)(1 + s/\omega_c)} \quad (54)$$

where

$$\begin{aligned} A_{cm} &\equiv \frac{D'(\omega_c L_e \parallel R \parallel R_L)}{R_f} = \frac{0.5(37.7 \parallel 11.2 \parallel 11.2)}{0.0813} \\ &= \frac{0.5 \times 4.88}{0.0813} = 30.0 \rightarrow 30 \text{ dB} \end{aligned} \quad (55)$$

$$\omega_p = \frac{1}{(\omega_c L_e \parallel R \parallel R_L)C} = \frac{10^3}{4.88 \times 2} = (2\pi)16.4 \text{ Hz} \quad (56)$$

$$A_g = A_{gm} \frac{1 + s/\omega_{zg}}{(1 + s/\omega_p)(1 + s/\omega_c)} \quad (57)$$

where

$$A_{gm} \equiv \frac{c_3(\omega_c L_e \| R \| R_L)}{D'R} = \frac{1.15 \times 4.88}{0.5 \times 11.2} = 1.00 \rightarrow 0 \text{ dB}$$

$$Z_o = R_{om} \frac{1}{1 + s/\omega_p} \quad (58)$$

where

$$R_{om} = (\omega_c L_e \| R \| R_L) = 4.88 \Omega \rightarrow 14 \text{ dB ref. } 1 \Omega. \quad (59)$$

These three functions are sketched in magnitude-asymptote form in Fig. 11.

VI. CURRENT-PROGRAMMED BOOST REGULATOR CLOSED-LOOP PROPERTIES

The model of Fig. 10 contains all the information necessary for the establishment of the major voltage loop gain, the regulator closed-loop output impedance Z_{of} , and line-to-output transfer function A_g .

A. Loop Gain T , Phase Margin ϕ_M , and Feedback Factor $1 + T$

The voltage loop gain T is simply the product of the error amplifier gain A_1 and the control-to-output transfer function A_c of the loaded power stage:

$$T = A_1 A_c. \quad (60)$$

If A_1 is a constant A_{1m} , the loop gain is merely a vertical scaling of the function A_c with its various corner frequencies. This is the same as saying that the value of A_{1m} determines not only the midband loop gain T_m as

$$T_m = A_{1m} A_{cm} \quad (61)$$

but also the loop gain crossover frequency $f_{vc} = \omega_{vc}/2\pi$, the frequency where the magnitude of T crosses the 0-dB axis, as shown in Fig. 12. By the geometry of the graph,

$$\omega_{vc} = T_m \omega_p. \quad (62)$$

The value of A_{1m} must be chosen so that crossover occurs below the RHP zero ω_z , because if it were above ω_z , the phase lag of T would exceed 180° and the regulator would be unstable. Obviously, one wishes to place the crossover frequency as close to ω_z as possible to get the widest bandwidth over which the benefits of feedback are realized.

Where shall the loop gain crossover frequency f_{vc} be placed? Let us try putting f_{vc} at about one-third of the RHP zero frequency $f_z = 2.29 \text{ kHz}$, say $f_{vc} = 750 \text{ Hz}$.

The resulting phase margin ϕ_M of the voltage loop gain is 180° minus the sum of the lag contributions from the poles at f_p and f_c , and the RHP zero at $f_z = 2.29 \text{ kHz}$:

$$\phi_M = 180^\circ - \left(\tan^{-1} \frac{750}{16} + \tan^{-1} \frac{0.75}{2.29} + \tan^{-1} \frac{0.75}{7.69} \right)$$

$$= 180^\circ - (89^\circ + 18^\circ + 6^\circ) = 67^\circ. \quad (63)$$

Fig. 11. Magnitude versus frequency asymptotes of open-loop loaded power stage transfer functions control-to-output $A_c \equiv \hat{v}/\hat{v}_c$, line-to-output $A_g \equiv \hat{v}/\hat{v}_g$, and output impedance Z_o , from model of Fig. 10.

Fig. 12. Placement of loop gain crossover frequency f_{vc} at 750 Hz, by appropriate choice of midband loop gain T_m and hence of error amplifier gain A_{1m} .

This is an acceptable phase margin, so we can adopt the crossover frequency $f_{vc} = 750 \text{ Hz}$ and use (62) to find the corresponding midband loop gain as $T_m = f_{vc}/f_p = 750/16.4 = 45.8 \rightarrow 33 \text{ dB}$. From (61), the required value of the error amplifier gain is $A_{1m} = T_m/A_{cm} = 45.8/30.0 = 1.53 \rightarrow 4 \text{ dB}$.

The error amplifier is actually an opamp with local feedback to set its overall gain A_1 , and hence the crossover frequency of the regulator major voltage loop. Since only 4.1 dB of gain is required, most of the available opamp gain is wasted. However, the lost gain can be recovered, for frequencies sufficiently far below the regulator loop crossover frequency, by placing an "inverted zero" ω_1 in the error amplifier gain function:

$$A_1 = A_{1m} \left(1 + \frac{\omega_1}{s} \right). \quad (64)$$

From the circuit in Fig. 2,

$$A_{1m} = R_a/R_b \quad (65)$$

$$\omega_1 = \frac{1}{C_a R_a} \quad (66)$$

The zero ω_1 is open to choice; let us make $\omega_1/2\pi = f_1 = 9.50$ Hz. Since A_{1m} is already set at 1.53 and $R_b = 47.5$ k is specified, the required values of R_a and C_a are

$$R_a = A_{1m} R_b = 1.53 \times 47.5 = 72.7 \text{ k} \quad (67)$$

$$C_a = \frac{1}{\omega_1 R_a} = \frac{10^{-3}}{2\pi \times 9.50 \times 72.7} = 0.230 \text{ } \mu\text{F}. \quad (68)$$

The final designed loop gain T is shown in Fig. 13. The inverted zero at $f_1 = 9.50$ Hz contributes a small additional phase lag $\tan^{-1}(9.50/750) = 0.7^\circ$ at the crossover frequency $f_{vc} = 750$ Hz, resulting in a negligible reduction in the original phase margin $\phi_M = 67^\circ$.

The expression for the final regulator voltage loop gain, by incorporation of (54) and (64) into (60), is

$$T = T_m \frac{\left(1 + \frac{\omega_1}{s}\right) \left(1 - \frac{s}{\omega_z}\right)}{\left(1 + \frac{s}{\omega_p}\right) \left(1 + \frac{s}{\omega_c}\right)} \quad (69)$$

where

$$\begin{aligned} T_m &\equiv A_{1m} A_{cm} = A_{1m} \frac{D'(\omega_c L_e \| R \| R_L)}{R_f} \\ &= 45.8 \rightarrow 33 \text{ dB}. \end{aligned} \quad (70)$$

Also, the regulator voltage loop crossover frequency is, from (56) and (62),

$$\begin{aligned} \omega_{vc} = T_m \omega_p &= \frac{A_{1m} D'}{R_f C} = \frac{1.53 \times 0.5 \times 10^6}{0.0813 \times 2000} \\ &= (2\pi) 750 \text{ Hz}. \end{aligned} \quad (71)$$

The above numerical results for T_m and ω_{vm} of course confirm the values that led to choice of A_{1m} in the first place. To complete the summary of analytical and numerical results, the expressions and numbers for the corner frequencies are repeated below:

$$\omega_p = \frac{1}{(\omega_c L_e \| R \| R_L) C} = (2\pi) 16.4 \text{ Hz} \quad (72)$$

$$\omega_c = \frac{\omega_s}{\pi n D'} = (2\pi) 7.69 \text{ kHz} \quad (73)$$

$$\omega_z = \frac{R}{L_e} = (2\pi) 2.29 \text{ kHz} \quad (74)$$

$$\omega_{zg} = \frac{c_3 \omega_s}{\pi D} = (2\pi) 18.3 \text{ kHz}. \quad (75)$$

Fig. 13. Construction of feedback factor $1 + T$ from loop gain T , after inverted zero chosen to be at $f_1 = 9.5$ Hz has been introduced into T , for minimum load resistance $R_L = R = 11.2 \text{ } \Omega$.

The regulator closed-loop output impedance Z_{of} and line-to-output transfer functions A_{gf} are given in terms of their respective open-loop values Z_o and A_g by

$$Z_{of} = \frac{Z_o}{1 + T} \quad (76)$$

$$A_{gf} = \frac{A_g}{1 + T} \quad (77)$$

where T is the regulator major voltage loop gain given by (69)–(75).

Only one additional calculation is required, which is to find the feedback factor $1 + T$ from the known T . As shown in Fig. 13, $1 + T$ can be constructed by drawing the asymptotes for $1 + T$ just above those of T for frequencies below the crossover f_{vc} . However, beyond crossover, T is much less than unity, so $1 + T \approx 1$ or 0 dB. All that remains is to identify the corner frequencies of $1 + T$. The inverted zero ω_1 and the lowest pole ω_p are the same as those in T ; the new zero, by the geometry of the asymptotes, is $(1 + T_m)f_p$ or $(1 + T_m)f_{vc}/T_m$. Hence the factored pole-zero expression for $1 + T$ can be written by inspection of the asymptotes as

$$1 + T = (1 + T_m) \frac{\left(1 + \frac{\omega_1}{s}\right) \left(1 + \frac{T_m s}{(1 + T_m)\omega_{vc}}\right)}{\left(1 + \frac{s}{\omega_p}\right)} \quad (78)$$

Note that if (69) for T were substituted into $1 + T$ and the pole-zero factors found algebraically, a cubic equation would have to be solved. With appropriate approximation, the result of (78) would be obtained.

B. Closed-Loop Transfer Functions Z_{of} and A_{gf} for Maximum Load

The regulator closed-loop output impedance Z_{of} can now be found from substitution of (58) and (78) into (76):

$$Z_{of} = R_{ofm} \frac{1}{\left(1 + \frac{\omega_1}{s}\right) \left(1 + \frac{T_m s}{(1 + T_m)\omega_{vc}}\right)} \quad (79)$$

where

$$\begin{aligned} R_{ofm} &= \frac{R_{om}}{1 + T_m} = \frac{T_m}{1 + T_m} \frac{R_{om}}{T_m} \\ &= \frac{T_m}{1 + T_m} \frac{R_f}{A_{1m} D'} \\ &= \frac{45.8}{46.8} \frac{0.0813}{1.53 \times 0.5} = 0.10 \Omega. \quad (80) \end{aligned}$$

Although the algebra is simple, more insight is gained into the above result if the process is conducted graphically. In Fig. 14, the magnitude asymptotes for Z_o and $1 + T$ are shown; their difference gives $Z_o/(1 + T) = Z_{of}$.

The same graphical process can be used to find the regulator closed-loop line-to-output transfer function. Fig. 15 shows the magnitude asymptotes of A_g and $1 + T$ from (57) and (78); their difference gives $A_g/(1 + T) = A_{gf}$. Analytically, the result is

$$\begin{aligned} A_{gf} &= A_{gfm} \frac{\left(1 + \frac{s}{\omega_{zg}}\right)}{\left(1 + \frac{\omega_1}{s}\right) \left(1 + \frac{T_m s}{(1 + T_m) \omega_{vm}}\right) \left(1 + \frac{s}{\omega_c}\right)} \quad (81) \end{aligned}$$

where

$$\begin{aligned} A_{gm} &\equiv \frac{A_{gm}}{1 + T_m} = \frac{T_m}{1 + T_m} \frac{A_{gm}}{T_m} \\ &= \frac{T_m}{1 + T_m} \frac{c_3 R_f}{A_{1m} D'^2 R} \\ &= \frac{45.8}{46.8} \frac{1.15 \times 0.0813}{1.53 \times 0.5^2 \times 11.2} \\ &= 0.021 \rightarrow -33 \text{ dB}. \quad (82) \end{aligned}$$

C. Closed-Loop Transfer Functions Z_{of} , A_{gf} for Minimum Load

The value of the design-oriented analysis approach is that the simple analytic results, directly in terms of the circuit elements, can be used both to select suitable design values and to determine the effects of different operating conditions.

In the previous section, such expressions were derived for the regulator closed-loop output impedance Z_{of} and line-to-output transfer functions A_{gf} in terms of the major voltage loop gain T . Numerical results were obtained for full-load operating conditions corresponding to $R_L = R = 11.2 \Omega$. It is of interest to determine the regulator performance functions at minimum load, defined in Section II-B as the load below which discontinuous conduction occurs, which corresponds to $R_L = R = 78 \Omega$. At the same time, the relevant analytical results can conveniently be gathered together.

Fig. 14. Construction of closed-loop output impedance Z_{of} from its open-loop value Z_o and feedback factor $1 + T$, according to $Z_{of} = Z_o/(1 + T)$, for $R_L = R = 11.2 \Omega$.

Fig. 15. Construction of closed-loop line-to-output transfer function A_{gf} from its open-loop value A_g and feedback factor $1 + T$, according to $A_{gf} = A_g/(1 + T)$ for $R_L = R = 11.2 \Omega$.

Current-Programmed Boost Regulator of Fig. 2—Parameters:

$$K = \frac{2L}{RT_s}. \quad (83)$$

At minimum load,

$$K = K_{crit} = DD'^2 = 0.5(0.5)^2 = 0.125 \quad (84)$$

and

$$R = R_L = 78 \Omega. \quad (85)$$

Hence

$$\omega_c L_e = \frac{KR}{nD'^3} = \frac{0.125 \times 78}{2.07 \times (0.5)^3} = 37.7 \Omega \quad (86)$$

and

$$\omega_c L_e \parallel R \parallel R_L = 37.7 \parallel 78 \parallel 78 = 19.2 \Omega \quad (87)$$

and

$$c_3 = 1 + \frac{R(1 - D/nD')}{\omega_c L_e} = 2.07. \quad (88)$$

Loop gain:

$$T = T_m \frac{\left(1 + \frac{\omega_1}{s}\right) \left(1 - \frac{s}{\omega_z}\right)}{\left(1 + \frac{s}{\omega_p}\right) \left(1 + \frac{s}{\omega_c}\right)} \quad (89)$$

where

$$T_m = A_{1m} \frac{D'(\omega_c L_e \parallel R \parallel R_L)}{R_f} = 1.53 \frac{0.5 \times 19.2}{0.081} = 180 \rightarrow 45 \text{ dB} \quad (90)$$

$$\omega_p = \frac{1}{(\omega_c L_e \parallel R \parallel R_L)} = \frac{10^6}{19.2 \times 200} = (2\pi)4.14 \text{ Hz} \quad (91)$$

$$\omega_c = \frac{\omega_s}{\pi nD'} = \frac{2\pi \times 25}{\pi \times 2.07 \times 0.5} = (2\pi)7.69 \text{ kHz} \quad (92)$$

$$\omega_z = \frac{R}{L_e} = \frac{78}{780} 10^6 = (2\pi)15.9 \text{ kHz} \quad (93)$$

$$\omega_1 = \frac{1}{R_a C_a} = \frac{10^3}{72.7 \times 0.230} = (2\pi)9.5 \text{ Hz}. \quad (94)$$

Loop gain crossover frequency:

$$\omega_{vc} = \frac{A_{1m} D'}{R_f C} = \frac{1.53 \times 0.5 \times 10^6}{0.0813 \times 2000} = (2\pi)750 \text{ Hz}. \quad (95)$$

Feedback factor:

$$1 + T = (1 + T_m) \frac{\left(1 + \frac{\omega_1}{s}\right) \left(1 + \frac{T_m s}{(1 + T_m)\omega_{vc}}\right)}{\left(1 + \frac{s}{\omega_p}\right)}. \quad (96)$$

Closed-loop output impedance:

$$Z_{of} = R_{ofm} \frac{1}{\left(1 + \frac{\omega_1}{s}\right) \left(1 + \frac{T_m s}{(1 + T_m)\omega_{vc}}\right)} \quad (97)$$

where

$$R_{ofm} = \frac{T_m}{1 + T_m} \frac{R_f}{A_{1m} D'} = \frac{T_m}{1 + T_m} \frac{1}{\omega_{vc} C} = \frac{180}{181} \frac{10^6}{2\pi \times 750 \times 2000} = 0.11 \Omega. \quad (98)$$

Closed-loop line-to-output transfer function:

$$A_{gf} = A_{gfm} \frac{\left(1 + \frac{s}{\omega_{zg}}\right)}{\left(1 + \frac{\omega_1}{s}\right) \left(1 + \frac{T_m s}{(1 + T_m)\omega_{vc}}\right) \left(1 + \frac{s}{\omega_c}\right)} \quad (99)$$

where

$$A_{gfm} = \frac{T_m}{1 + T_m} \frac{c_3 R_f}{A_{1m} D'^2 R} = \frac{T_m}{1 + T_m} \frac{c_3}{D' R} \frac{1}{\omega_{vc} C} = \frac{180}{181} \frac{2.07}{0.5 \times 78} \frac{10^6}{2\pi \times 750 \times 2000} = 0.056 \rightarrow -45 \text{ dB} \quad (100)$$

$$\omega_{zg} = \frac{c_3 \omega_s}{\pi D} = 2\pi \frac{2.07 \times 25}{\pi \times 0.5} = (2\pi)32.9 \text{ kHz}. \quad (101)$$

VII. DISCUSSION OF THE MODEL AND THE RESULTS

A. Remarks on the Effectiveness of Current Programming

In accordance with the preferred approach outlined in Section II-A the regulator voltage feedback loop is explicitly exposed, while the current feedback loop has been absorbed into the model representing the overall properties of the current-programmed power stage. One of the advantages of this form is that the properties of the current-programmed power stage are immediately visible, which is why the three functions A_c , A_g , and Z_o could be written directly by inspection of the model.

Also, it can be seen how well the current programming does its intended job of making the output current "constant." What this objective really means is that the output current should be represented in the model by a current generator proportional to the control voltage \hat{v}_c . It is seen that such a current generator (the y_{2c} generator) is indeed present, but that the output current is not equal to it because the output resistance is not infinite.

For the buck converter, the output resistance is $\omega_c L / (1 - D/nD')$ and, as shown in [6], the denominator only goes to zero in the limit of instability when $n \rightarrow D/D'$. Therefore, the output resistance can only go to infinity if either the switching frequency or the inductance goes to infinity, a limit that corresponds to infinite loop gain of the current minor feedback loop [6]. The actual value of the output resistance $\omega_c L / (1 - D/nD')$ in the present example is 1.5Ω , and not at all large, consistent with the point made in [6] that the low-frequency current loop gain is not large.

For the boost converter, the output resistance consists of two resistances in parallel, $\omega_c L_e$ and R . The resistance $\omega_c L_e$ goes to infinity only if either the switching frequency or the inductance goes to infinity, a limit that corresponds to infinite loop gain of the current minor feedback loop [6]. The actual value in the present example $\omega_c L_e = 37.7 \Omega$ is not very large, also consistent with [6]. However, even if there were infinite current loop gain, so that $\omega_c L_e \rightarrow \infty$, the output of the current-programmed power stage would still not be an ideal current source because of the remaining resistance R across the output. This reflects the fact, also pointed out in [6], that the current being "programmed" in the boost converter is not the output current but the input current (note that in (49) y_{11} does go to zero, although y_{22} does not, as $\omega_c L_e \rightarrow \infty$).

Finally, the current generator $y_{2c} \hat{v}_c$ itself in Figs. 4 and 10 fails to "program" its current at higher frequencies, because of the pole ω_c and, in the boost converter, also because of the RHP zero ω_z . As already mentioned, this pole is the crossover frequency of the current loop gain, that is, the frequency above which the current-programming ceases to function at all. Consequently, the control-to-output transfer function A_c given by (16) and (54) contains not only the dominant pole ω_p (commonly thought to be the "only corner frequency" in this function), but also a second pole ω_c , as shown graphically in Fig. 5 for the buck converter, and the second pole and RHP zero ω_z for the boost, shown in Fig. 11.

Were it not for these "shortcomings" of the current feedback loop, the $y_{2c} \hat{v}_c$ current generator in Fig. 4 for the buck would be $1/R_f$, and this would also be the output current, so that the output current would ideally be programmed to be equal to $(1/R_f) \hat{v}_c$. In Fig. 10 for the boost, the $y_{2c} \hat{v}_c$ current generator would be D'/R_f , so that the output current would be programmed to be equal to $(D'/R_f) \hat{v}_c$. The D' occurs because it is actually the input current being programmed, which is D' times the output current.

Thus R_f , the effective current sense resistance, sets the control voltage to output current gain, and therefore appears as an explicit (reciprocal) factor in the control voltage to output voltage transfer function given by (16) and (17) for the buck, and (54) and (55) for the boost. This transfer function implicitly applies to the power stage with the minor current-programming feedback loop closed, just as the gain block labeled "error amplifier" in Figs. 1 and

2 applies to the error amplifier with its minor voltage feedback loop closed.

In this way, the various feedback loops are accounted for in an orderly fashion, and in the models of Figs. 4 and 10, only the regulator major voltage feedback loop remains to be considered. This is done in the familiar manner used for conventional "single-loop" regulators, the only difference being the incorporation of a different canonical model for the power stage.

B. Significance and Interpretation of the Design-Oriented Analysis

Analysis is only one of the tools used in design, and analysis is only useful if its results can be used in reverse to select element values to achieve certain performance results, namely, to meet the specifications.

The interpretation of the analytic results obtained above, discussed in this section, is indispensable if full value is to be obtained from the analysis. This is, after all, the whole purpose of the "design-oriented analysis" approach.

The most important aspects of the analytic results are the loop gain crossover frequency and the midband (maximum) values of the closed-loop output impedance and line-to-output transfer function, and how they vary from minimum to maximum load resistance and from minimum to maximum line voltage. The load resistance R_L enters the equations directly, and also indirectly through the operating point parameter R , which for a purely resistive load is numerically equal to the load resistance R_L . The line voltage enters the equations through the duty ratio D needed to maintain the regulated output voltage $V = 15$ V.

Although the midband loop gain T_m of the buck regulator, by (33), varies quite strongly with both D and R_L , the crossover frequency $\omega_{vc} = A_{1m}/R_f C$, by (35), is independent of both line and load. This is because the dominant pole ω_p , (37), varies inversely with T_m as the same function of D and R_L through the common factor $[\omega_c L / (1 - D/nD')] \parallel R_L$. It is, of course, desirable to have a crossover frequency that changes little, if at all, with operating conditions. Similar remarks apply to the boost regulator, except that the D dependence is absent.

On the other hand, the midband loop gain T_m itself does not have any particular significance because it is explicit only over the narrow frequency range between the inverted zero ω_1 and the dominant pole ω_p . The final pole ω_c in the loop gain is also independent of load but does depend on line voltage. In the boost regulator, at the minimum load condition of Fig. 16, T_m does not even appear explicitly because the (load-dependent) pole ω_p has dropped below the (fixed) inverted zero ω_1 . The RHP zero ω_z increases in proportion to the load resistance, by (93).

In the boost regulator, although the loop gain crossover frequency is independent of load, the phase margin changes because two of the four corner frequencies change with load. At maximum load resistance (minimum load

Fig. 16. Loop gain T and feedback factor $1 + T$ for maximum load resistance $R_L = R = 78 \Omega$. Compared to minimum load resistance case of Fig. 13 dominant pole f_p has moved below inverted zero f_i , and RHP zero f_z has moved above current loop-gain crossover frequency f_{vc} .

current), the phase margin is

$$\begin{aligned} \phi_M &= 180^\circ - \left(\tan^{-1} \frac{9.5}{750} + \tan^{-1} \frac{750}{4.14} \right. \\ &\quad \left. + \tan^{-1} \frac{0.75}{15.9} + \tan^{-1} \frac{0.75}{7.69} \right) \\ &= 180^\circ - (0.7^\circ + 90^\circ + 3^\circ + 6^\circ) = 80^\circ. \end{aligned} \quad (102)$$

Interestingly, not only does the midband loop gain T_m increase with load resistance, but so does the phase margin; at minimum load resistance the phase margin is 67° , (63), and the (fixed) contributions of the inverted zero ω_i from the error amplifier and of the current loop-gain crossover frequency ω_c are negligible at both extremes of load. The increase in ϕ_M at higher load resistance essentially results from the movement of the power stage RHP zero ω_z further beyond the crossover frequency ω_{vc} .

In both regulators, the feedback factor $1 + T$ essentially follows T until it levels out at unity at the zero $(1 + T_m)\omega_{vc}/T_m$, by (41) and (96). Even at maximum load resistance, the midband loop gain is sufficiently high that $(1 + T_m)/T_m \approx 1$ and so $1 + T$ levels out at essentially the crossover frequency f_{vc} .

The closed-loop output impedance Z_{of} is its open-loop value divided by the feedback factor, which results in (42) and (79). Since the loop gain goes away at the crossover frequency, the closed-loop output impedance is essentially equal to its open-loop value beyond ω_{vc} ; since its open-loop value is dominated by the load capacitance C the midband (maximum) closed-loop value R_{ofm} is equal to the load capacitance reactance at the frequency $(1 + T_m)\omega_{vc}/T_m$, as seen from Eqs. (43) and (80). The closed-

loop output impedance drops below R_{ofm} at decreasing frequencies below ω_i because the error amplifier gain increases, and so the loop gain increases faster than the capacitance reactance.

The most significant consequence of these points is that the closed-loop output impedance Z_{of} is independent of load R_L (and of the operating point parameter R), to the extent that $(1 + T_m)/T_m \approx 1$.

Very similar remarks may be made concerning the closed-loop line-to-output transfer function A_{gf} of (44) and (81), which is also equal to its open-loop value divided by the feedback factor. The midband (maximum) closed-loop value A_{gfm} is equal to its open-loop value at the frequency $(1 + T_m)\omega_{vc}/T_m$, as seen from (45) and (82). For the buck regulator, as in the case of the output impedance, this maximum value does not depend on the operating point parameter R . For the boost regulator, unlike in the case of the output impedance, however, this maximum value does depend on the operating point parameter R , both explicitly by (82), and implicitly through c_3 by (88). The closed-loop line-to-output transfer function A_{gf} is smaller at maximum than at minimum load resistance.

Some further points can be made regarding the design choices. The central importance of the loop gain crossover frequency has been emphasized: it determines the midband value of the closed-loop output impedance and of the line-to-output transfer function, and the pole above which they fall off. Clearly, it is desirable to have as high a crossover frequency f_{vc} as possible. In the buck regulator, the maximum crossover frequency is limited by its encroachment on the second pole ω_c of the power stage and consequent reduction of phase margin. In the boost regulator, the crossover frequency is limited by its encroachment on the RHP zero ω_z of the power stage, with consequent reduction of phase margin. Because ω_z increases with load resistance, the worst-case in this respect occurs at minimum load resistance, for which the design choice $\omega_{vc} \approx \omega_z/3$ was made, and which directly sets the required midband gain A_{1m} of the error amplifier.

The other frequency of salient importance is the error amplifier inverted zero at f_i . It is desirable to have f_i as high as possible to make as narrow as possible the frequency over which the closed-loop output impedance and line-to-output transfer function have their maximum values (Figs. 8, 9, 14, 15, 17, and 18). The limiting factor is again phase margin; a higher f_i reduces ϕ_M . The design choices of A_{1m} and f_i are implemented by the appropriate values of R_a and C_a in the error amplifier circuit of Figs. 1 and 2, as given by (30), (31) and (67), (68).

The consequence of too low a phase margin, whether because of proximity of either the second pole ω_c or the inverted zero f_i to the crossover frequency f_{vc} , is that both the closed-loop output impedance and line-to-output transfer functions develop a resonant peak above their midband values. In the extreme, of course, instability results.

Consideration has been given here mainly to the effects of load resistance upon the regulator performance func-

Fig. 17. As Fig. 14 but for $R_L = R = 78 \Omega$.Fig. 18. As Fig. 15 but for $R_L = R = 78 \Omega$.

tions. However, all the information relevant to the current-programmed buck regulator of Fig. 1 is contained in the model of Fig. 4. A complete design should of course also take into account a range of line voltages V_g , which would be accounted for in the model by a corresponding range of duty ratio D .

Other choices of stabilizing ramp slope M_c , represented through the parameter n of (5), could also be considered. It has already been mentioned in Section II-B that the buck power stage is overstabilized in the sense that M_c exceeds M_2 , the declining inductance current slope during the

power switch off-time. The power stage is even more overstabilized in another sense, related to the line-to-output transfer function A_g .

As seen from Fig. 4 and (20), the line-to-output transfer function A_g contains the factor $(1 - 1/nD')$ (from the y_{21} element of the y parameter model of the current-programmed power stage). This factor is zero if $nD' = 1$. From (5), this occurs if the stabilizing ramp slope is chosen to be $M_c = M_{co}$ such that

$$M_{co} = \frac{1}{2} \frac{D}{D'} M_1 = \frac{1}{2} M_2 = \frac{1}{2} \frac{V}{L}. \quad (103)$$

In the example regulator, this corresponds to a voltage stabilizing ramp amplitude $V_p = 0.76$ V, rather than the original value $V_p = 2.0$ V. Moreover, this optimum value is independent of operating point for a given regulated output voltage.

Almost all the numbers in the example circuits of Figs. 1 and 2 are the same as those used by Schoneman and Mitchell [7], who presented experimental measurements of the closed-loop output impedance and line-to-output transfer function to verify predictions made by an entirely different modeling approach.

The only regulator design parameter in this paper chosen differently from that of Schoneman and Mitchell is the error amplifier midband gain $A_{1m} = R_a/R_b$, which is here set at $A_{1m} = 2.84$ with a required resistance $R_a = 270$ k, for the buck regulator, and $A_{1m} = 1.53$ with $R_a = 72.7$ k for the boost. The value of C_a here is different from that of Schoneman and Mitchell only to maintain the same value of the inverted zero $f_i = 11$ Hz for the buck and $f_i = 9.5$ Hz for the boost.

Although the regulator properties and transfer functions derived in this paper have not been directly verified experimentally by the author, they agree completely with the experimental measurements presented by Schoneman and Mitchell when their values $A_{1m} = 78.7/95.3 = 0.83$ for the buck and $A_{1m} = 12.4/47.5 = 0.26$ for the boost are employed. This may be taken to be adequate proof of the validity of the canonical models for the current-programmed power stages of Figs. 4 and 10.

There is actually one other difference from the model of Schoneman and Mitchell. In the circuit of Figs. 1 and 2, the resistance 0.012Ω in series with the capacitance C gives a zero at $\omega_2 = (2\pi)6.7$ kHz for the buck and $\omega_2 = (2\pi)5.0$ kHz for the boost regulator, which has been ignored throughout this paper to eliminate the corresponding factor from numerous equations. It could easily be replaced, and would appear as a factor $(1 + s/\omega_2)$ in the numerators of the expressions for the loop gain and the open-loop and closed-loop output impedance and line-to-output transfer functions.

Both the modeling approach employed in this paper and that of Schoneman and Mitchell are based on state-space averaging method for switched-mode converters [8]. This means that results at frequencies approaching the switching frequency $f_s = 25$ kHz are not reliable.

VIII. CONCLUSION

Current-programming of switching power stages is becoming widely adopted. However, application of more recently presented equivalent circuit models has not been fully developed. This paper discusses the use of a particular model for the power stage in the analysis and design of current-programmed buck and boost regulators.

Since current-programming introduces a minor feedback loop around the power stage, which is inside the regulator major voltage loop, a choice must be made at the outset as to which loop or combination of loops are to be adopted for analysis purposes. The merits of alternative choices are discussed in Section II, and additional comments are offered in [10].

The approach chosen is that in which the current-programming minor loop is absorbed into an equivalent circuit (canonical model) that represents the properties of the current-programmed power stage as a whole. The benefit gained is that the degree to which the current-programming is effective can immediately be seen explicitly from this model, which then becomes one transfer block in the model of the regulator major voltage feedback loop. From there, the familiar methods for single-loop feedback systems can be employed. The simplicity of this approach is of significant value in the method of design-oriented analysis, in which the analytic results (which are not "answers" in themselves) can be used in reverse to make design choices and tradeoffs.

This procedure is pursued in the following sections, applied for illustration to a 150-W current-programmed buck regulator and a 280-W boost regulator switched at 25 kHz.

In Section III the y-parameter canonical model for a current-programmed power stage is modified and simplified for specific application to the example buck converter and immediately leads to simple factored pole-zero expressions for the control-to-output and line-to-output (audiosusceptibility) transfer functions A_c and A_g , and for the power-stage output impedance Z_o .

These open-loop functions are used in Section IV to determine the regulator (single-)loop gain T and, by a simple semigraphical technique, the feedback factor $1 + T$. The feedback factor in turn is used to find the regulator closed-loop properties of Z_{of} and A_{gf} that correspond to the converter open-loop values, by $Z_{of} = Z_o / (1 + T)$ and $A_{gf} / (1 + T)$.

In Sections V and VI corresponding procedures are followed for the example boost regulator.

These steps represent the essence of the design-oriented analysis approach, in which the analytic results, which are to match the specifications, are in simple forms closely related to the original elements in the system. The significance and interpretation of the design-oriented analysis approach as applied to the example regulator are discussed at some length in Section VII.
